Case Report
A rare pediatric case of a thymic cytotoxic and lymphoblastic T/NK cell lymphoma

Abstract: Attempts to establish a concise classification of lymphoblastic lymphomas (LBLs) have gained momentum in recent years, mainly due to the expanding possibilities of immunohistochemical and genetic characterization of different disease entities. Thus, cases of immature lymphoid malignancies with unusual immunopathological features have been reported during the last years, suggesting the need for new LBL classification concepts. To further characterize and demonstrate the extended spectrum of LBL, we present an unusual pediatric case of LBL that could not be categorized into one of the subgroups and exhibited a benign course after surgical treatment and subsequent chemotherapy. A mediastinal tumor of a 6-year-old Caucasian boy was examined by clinical staging, light microscopy, immunohistochemistry and PCR assays. The tumor cells reacted with TdT and had a positive cytoplasmic immunoreactivity for CD3. Further T- and NK-cell markers CD1a, CD4, CD8, CD10, and CD56 reacted positively, but CD57, CD16 and CD30 (Ber H2) were all negative. CD34 as a marker for bipotential B/T-precursors was also positive. B cell markers (CD20, CD22, CD79a and IgM) were all negative. No clonal B cell Ig or T cell gamma chain rearrangements were detectable. Epstein Barr virus and other Herpes Virus DNA were not detected using a sensitive PCR assay. The applied chemotherapy was tolerated well and a complete remission of the tumor was achieved (observation period three years after the initial diagnosis). Localization, morphology, and the expressions markers made the tumor a typical member of the LBL group. However, our case represents a rare pediatric lymphoma derived from a thymic precursor committed to T/NK-cell differentiation and a favourable outcome after chemotherapy.

Keywords: lymphoblastic lymphomas, T/NK cell lymphoma, pediatric lymphoma

Introduction

Lymphoblastic lymphoma (LBL) is a distinct category of non-Hodgkin lymphoma derived from a lymphocytic precursor. It was first discovered by Sternberg [1] and clinically characterized by Cooke [2]. Only 4% of the non-Hodgkin lymphomas are considered to be LBLs and the majority of them has a thymic T-cell origin [3]. Sheibani et al [4] classified the LBLs into five subgroups based on their immunophenotype: 1. T-LBL (expression of only T cell-associated antigens); 2. T-LBL with expression of common acute lymphoblastic leukemia antigen (expression of T-associated antigens with CD10); 3. Natural killer (NK)-LBL (expression of CD16 with or without T-associated antigens); 4. Pre-B-LBL (expression of CD24 without T-associated antigen); 5. B-LBL (expression of monoclonal surface membrane immunoglobulin, IgM, without terminal deoxynucleotidyltransferase (TdT)).

Recently, following the discovery of further phenotypic markers and new antibodies, a more detailed immunophenotypic analysis has become possible and new entities have been proposed [5]: 1. CD7+ blastic stem cell leukemia (a pluripotent stem cell malignancy) [6]; 2. Blastic NK cell lymphoma (own entity in the new WHO classification of lymphomas) [7]; 3. Myeloid NK cell precursor cell leukemia (derived from a myeloid antigen-positive precursor preceeding a NK cell precursor) [8]; 4. CD4+ CD56+ hemato-dermic lymphoma (derived from precursor cells related to plasmacytoid monocytes) [9]. All of these subtypes share an aggressive clinical course with rapid systemic involvement and a

poor prognosis. The close relationship between T-cells and NK-cells in the fetal thymus has been vigorously studied and there is common agreement that within human fetal thymocytes there is a population of T-cell/NK-cell (T/NK) bipotential progenitors with the ability to differentiate into T cells and NK cells through further separate precursors [10-12]. These bipotential progenitors can be characterized by the phenotype of CD3+, CD7+, CD13+, CD33+, CD34+, CD38+, HLA-DR+/−, CD2+/-, CD5+/-, CD28+/-, CD1-, no T cell receptor (TCR) gene rearrangement or CD56/CD16 expression [13]. Here, we describe a rare pediatric case of LBL with similar pheno/genotype of committed T/NK cell precursors and a surprisingly favorable prognosis after surgical treatment and subsequent chemotherapy.

Case history

A 6-year-old previously healthy boy presented with oligoarthritic joint pain, fever of 38°C and weight loss. Chest x-ray showed significantly enlarged mediastinal lymph nodes. Computed tomography and magnetic resonance imaging (MRI) revealed a 6x5x3cm mass in the anterior mediastinum compressing the Vena cava superior. Further physical examination, bone marrow biopsy, and scintigraphy revealed no evidence of bone marrow involvement.

Lymph node extraction near the M.sternocleido-mastoideus and subsequently pathological examination showed an unspecific lymphadenitis. The thereafter performed thoracotomy disclosed a solid tumor mass caudal of the thymus extending to the jugulum and infiltrating the vena cava superior. Further physical examination, bone marrow biopsy, and scintigraphy revealed no evidence of bone marrow involvement.

Lymph node extraction near the M.sternocleido-mastoideus and subsequently pathological examination showed an unspecific lymphadenitis. The thereafter performed thoracotomy disclosed a solid tumor mass caudal of the thymus extending to the jugulum and infiltrating the vena cava superior. The tumor and parts of the vena cava were resected, yielding a macroscopic R0 resection. Without suffering from postoperative complications the patient received a polychemotherapy according to the NHL-BFM 95 protocol [14]. The chemotherapy was tolerated well and a complete remission of the tumor was achieved. Regular follow-ups during an observation period of three years showed no recurrence of the tumor until now.

Materials and methods

Immunohistochemical analysis was performed on Formalin-fixed, paraffin-embedded tissue sections. Immunostaining was done with the following monoclonal antibodies: CD1a, CD8, CD20, CD22, CD79a, CD56, CD30, MiB1(Dako, Glostrup; Denmark), c-Kit, Tdt, CD2, CD4, CD3, CD5, CD16, CD34, CD43, Granzyme B (Novocastra, Newcastle; UK), TIA-1 (Coulter, Hialeah; USA), CD57 (Becton-Dickinson, San Jose; USA). Antibody binding was visualized using the Envision System (Dako, Glostrup; Denmark) system as described by the manufacturer. Herpes Virus, TCR gene rearrangement and B cell clonality PCR assays were performed as published previously [15-17].

Pathologic and immunohistochemical findings

Macroscopically, the specimen removed from the anterior mediastinum was a 7x6x4cm tumor with pseudo capsule. On the cut surface, the tumor was heterogeneous with yellow and white areas. Histologically, the tumor consisted of diffuse and monotonous proliferation of round or polyhedral - shaped lymphoid cells surrounded by a pseudo capsule and abundant necrosis. The chromatin was finely dispersed within the nucleus. Marginally, normal thymus tissue was resected, infiltrated by single tumor cells.

The tumor cells were positive for Tdt, cytoplasmic immunoreactivity for CD3 and the cytotoxic effector molecule TIA-1. Granzyme B was negative. Membranous CD3 reactivity was not detectable. Of the typical T cell differentiation markers CD1a, CD4, CD8 and CD10 reacted positively. CD34 as a marker for bipotential B/T-precursors was also positive.

The NK cell markers CD56 and CD2 were positive within the tumor cells, but CD57 and CD16 were all negative, suggesting an immature NK cell phenotype [18]. CD 30 (Ber H2) was negative. The proliferation fraction (MIB-1 index) was about 80%. B cell markers (CD20, CD22, CD79a and IgM) were all negative. No clonal B cell or T cell gamma chain rearrangements were detectable. Epstein Barr virus and other Herpes Virus DNA were not detected using a sensitive PCR assay [15]. Results of the immunohistochemical and PCR assays are summarized in Table 1 and Figure 1.

Discussion

The anatomical site of the tumor in the anterior mediastinum, the lack of any other tumor foci

and the expression of TdT suggested that it originated from the thymus. Based on this and the histological appearance of the tumor cells resembling lymphoblasts (monomorphic, medium seized cells with high N/C ratio and finely dispersed chromatin) we classified the tumor as LBL. Furthermore, the tumor combined immunophenotypical characteristics of a blastic/immature with a mature lymphoma. The lymphoblasts exhibited a unique set of markers, combining features of the T cell lineage with features of NK cell precursors. The coexpression of CD1a, CD4 and CD8 suggested a T cell precursor similar to the so called early double positive cells (EDP) by the model of Res and Spits [12], but without demonstrating the rearrangement of the TCR gamma, which is normally present at this stage [19]. TdT, CD3 and CD34 are antigens commonly expressed by cells at an early developmental stage, the antigen CD34 disappears when cells differentiate from bipotential T/NK progenitors to precursors of T or NK cells [13, 20]. Interestingly, the tumor cells in our case still expressed CD34. This suggests that, phenotypically, the lymphoma cells did not fully progress out of the stage of the bipotential T/NK progenitors. Besides, the neoplastic cells coexpressed NK cell lineage features (CD2, CD56) [21, 22].
Based on these findings, it appears that the lymphoma cells of this case have differentiated towards NK cells, although they were negative for CD16 or CD57. But CD16 and CD57 are not clearly associated with NK-cell precursors according to the model of NK cell development [23]. However, the expression of CD56 is not common in malignant lymphomas and usually identifies a group of lymphomas with distinctive clinicopathologic features. These lymphoma commonly affects middle-aged adults presenting with fever, skin rash, hepatosplenomegaly and an association with EBV infection [24].

Our case did not fit into this group of NK lymphomas due to the following features: (1) the histologic and cytologic appearance was that of a LBL, confirmed by expression of TdT with lymphoblastic morphology, (2) EBV DNA was not (3) azurophilic cytoplasmic granules were not found (4) the phenotype is that of T precursor cells, and (5) the age of the patient.

A possible relationship with a T-cell lymphoma seemed unlikely since a TCR rearrangement, cutaneous lesions or hepatosplenomegaly were not detected. Although cases of LBL with combined T and NK cell features have already been published [25, 26], this case of a thymic lymphoma is unique by combining the features of different developmental stages and lineages as well as the pediatric age of the patient.

We conclude that our case represents a novel pediatric lymphoma derived from a thymic precursor committed to T/NK-cell differentiation with a favourable outcome after postoperative adjuvant chemotherapy.
