Abstract: The author investigated histopathology of 1,464 consecutive rectal specimens in our pathology laboratory in Japan. A review of pathological reports was done by computer. Observation of histological slides was performed, when appropriate. The rectal specimens were composed of 1,041 benign lesions and 423 malignant lesions. The 423 malignant lesions were composed of 367 cases of primary rectal carcinoma, 41 cases of carcinoma in adenoma, 7 cases of neuroendocrine tumor, 3 cases of malignant lymphoma, 2 cases of gastrointestinal stromal tumors (GIST), and 3 cases of metastatic carcinoma. Of the 367 cases of primary rectal carcinoma, 37 cases were early carcinomas whose invasion was limited up to the submucosa (early rectal carcinoma). The remaining 330 cases were advanced carcinoma invading beyond the proper muscle layer. The histological types were well differentiated adenocarcinoma in 197 cases, moderately differentiated adenocarcinoma in 129 cases, poorly differentiated adenocarcinoma in 10 cases, mucinous adenocarcinoma in 24 cases, signet ring cell carcinoma in 6 cases, squamous cell carcinoma in 1 case in the 41 cases of carcinoma in adenoma, the carcinoma was well to moderately differentiated adenocarcinoma, and all cases were early carcinomas without invasion or with little invasions to subserosa. The size of carcinoma in adenoma was as follows: < 10 mm, 5 cases; 10-15 mm, 8 cases; 15-20 mm, 23 cases; > 20mm, 5 cases. The background adenoma was as follows: tubular adenoma (n=15), tubulo-villous adenoma (n=14), and villous adenoma (n=12). The 7 cases of neuroendocrine carcinoma consisted of 6 low grade neuroendocrine tumors (carcinoids) and 1 high grade neuroendocrine carcinoma (small cell carcinoma). All were submucosal lesions. Immunohistochemically, the tumor cells were positive for two or more of synaptophysin, chromogranin, neuron-specific enolase, CD56. In small cell carcinoma, KIT and PDGFRA were consistently positive. The 3 cases of malignant lymphoma were diffuse large B-cell lymphomas positive for CD20 and CD79a and negative for NK/T cell markers. The two cases of GIST was spindle cell type, and the risk was intermediate. KIT mutations were recognized in both GISTs. No PDGFRA mutations were seen. Of the 3 metastatic carcinomas, one was a metastasis from prostatic adenocarcinoma, and the remaining two was adenocarcinoma of unknown primary sites.

Keywords: Rectum, malignant lesions, histopathology

Introduction

Malignant lesions of the rectum include intraepithelial neoplasms (dysplasia), adenocarcinoma, mucinous adenocarcinoma, signet ring cell carcinoma, small cell carcinoma, squamous cell carcinoma, adenosquamous cell carcinoma, medullary carcinoma, undifferentiated carcinoma, neuroendocrine neoplasms (carcinoid), mixed carcinoid-adenocarcinoma, carcinoma in adenoma, gastrointestinal stromal tumor (GIST), leiomyosarcoma, angiosarcoma, Kaposi’s sarcoma, malignant melanoma, malignant lymphomas, and secondary malignant tumors [1, 2]. In the present study, 423 malignant conditions of the rectum were described.

Materials and methods

The author investigated histopathology of 1,464 consecutive rectal specimens in the last 10 years of our pathology laboratory. The rectal specimens were composed of 1,041 benign lesions and 423 malignant lesions. Clinical records were also reviewed. The age ranged from 18 years to 95 years with a mean of 54
years. In appropriate cases, an immunohistochemical analysis had been performed with the use of Dako Envision method (Dako), as previously described [3-7].

In GIST and neuroendocrine carcinoma cases, a molecular genetic analysis of KIT gene (exons 9, 11, 13, and 17) and PDGFRA (exons 12 and 18) gene was performed by the PCR direct sequencing method, as previously reported [6, 7]. The exons of both genes were selected because they are frequent mutation sites [8-13].

Results

The author investigated histopathology of 1,464 consecutive rectal specimens in the last 10 years of our pathology laboratory. The review of the pathological diagnosis was done by a computer. Examination of histological slides was performed when appropriate. The rectal
Rectal malignant conditions

specimens were composed of 1,041 benign lesions and 423 malignant lesions.

The 423 malignant lesions were composed of 367 cases of primary rectal carcinoma, 41 cases of carcinoma in adenoma, 7 cases of neuroendocrine tumor, 3 cases of malignant lymphoma, 2 cases of GIST, and 3 cases of metastatic carcinoma.

Of the 367 cases (frequency of all rectal malignancies, 86.8 %) of primary rectal carcinomas, 37 cases (8.7 %) were early carcinomas whose invasion was limited up to the submucosa. The remaining 330 cases (78%) were advanced carcinomas invading beyond the proper muscle layer. The histological types were well differentiated adenocarcinoma in 197 cases, moderately differentiated adenocarcinoma in 129 cases, poorly differentiated adenocarcinoma in 10 cases, mucinous adenocarcinoma in 24 cases, signet ring cell carcinoma in 6 cases, squamous cell carcinoma in 1 case.

In the 37 cases of early carcinoma, the gross features were classified into polypoid (n=14) (Figure 1A) and ulcerating (n=23) (Figure 1B). Histologically, 36 cases were adenocarcinoma and 1 case is squamous cell carcinoma (Figure 1C). Of the 36 adenocarcinomas, 21 were well differentiated adenocarcinomas (Figure 1D), and 15 were moderately differentiated adenocarcinomas (Figure 1E). Lymphovascular permeation was little or none in all cases, and lymph nodes dissected (n=18) showed no metastases. Immunohistochemically, p53 protein was present in 8/10 cases, and Ki-67 labeling ranged from 32 to 64 % in the 10 cases examined.
Rectal malignant conditions

In the 330 advanced carcinoma cases, the gross features were polypoid (Figure 2A) in 23 cases and ulcerated (Figure 2B) in 307 cases. Histologically, 179 cases were well differentiated adenocarcinomas (Figure 2C), 114 cases were moderately differentiated adenocarcinomas (Figure 2D), and 10 cases were poorly differentiated adenocarcinomas (Figure 2E). 24 cases were mucinous adenocarcinomas (Figure 2F), and 6 cases were signet ring cell carcinomas (Figure 2G). The depth of invasion was serosa in 25 cases, subserosa in 263 cases, and proper muscle in 42 cases. Lymphovascular invasions were recognized in 312 cases of the 330 cases, and lymph node metastases were present in 156 cases of the 298 cases dissected. Immunohistochemically, the poorly differentiated adenocarcinoma and signet ring cell carcinoma were positive for cytokeratins and negative for lymphocytic markers. Signet ring cell carcinoma and mucinous adenocarcinoma contained neutral and acidic mucins as revealed by mucin stains. The p53 was present in 13 cases of the 15 cases examined, and Ki-67 labeling ranged from 26% to 87% in the 15 cases examined. Multiple rectal carcinoma was recognized in one case (Figure 2H), and 5 cases showed synchronous colon carcinomas other than the rectum (Figure 2I).

In the 41 cases (5.6 %) of carcinoma in adenoma (Figure 3A), the carcinoma is well to moderately differentiated adenocarcinoma (Figure 3B), and all cases were early carcinomas with little invasions. The size of carcinoma in adenoma was as follows: < 10 mm, 5 cases; 10-15 mm, 8 cases; 15-20 mm, 23 cases; > 20mm, 5 cases. Histologically, the background adenoma was as follows: tubular adenoma (n=15), tubulo-villous adenoma (n=14), and villous adenoma (n=12). The atypia of the background adenoma is severe (high grade dysplasia) in all cases. Immunohistochemically, p53 protein was positive in carcinoma areas in 4 cases out of 5 cases examined. The Ki-67 labeling in carcinoma areas ranged from 10% to 36%, while that of adenoma areas from 8% to 15%.

The 7 cases (1.7%) of neuroendocrine carcinoma showed submucosal tumors in all cases (Figure 4A). Histologically, they consisted of 6 low grade neuroendocrine tumors (carcinoids) (Figure 4B) and 1 high grade neuroendocrine carcinoma (Figure 4C). The former showed a trabecular organoid pattern (Figure 4A and 4D) and rosette formations (Figure 4D) and ribbon-like features (Figure 4D), while the latter showed no apparent patterns (Figure 4B) equivalent to high grade neuroendocrine carcinoma (small cell carcinoma). Immunohistochemically, the tumor cells were positive for two or more of synaptophysin, chromogranin, neuron-specific enolase, CD56. KIT and PDGFRA were consistently positive (Figure 4E and 4F).

The 3 cases (0.7%) of malignant lymphoma were diffuse large B-cell lymphomas. Grossly, they assumed polypoid or ulcerated appearances (Figure 5A), similar to rectal carcinoma. Histologically, atypical large malignant lymphoid cells were seen to diffusely proliferate (Figure 5B) in all cases. There were many mitotic figures (Figure 5B). Immunohistochemically, the tumor cells were negative for cytokeratins.
and positive for CD45, CD20, CD79α (Figure 5C). Light chain restriction was present in all cases. The tumor cells were negative for CD3, TdT, and CD45RO. Marginal zone lymphoma, mantle cell lymphoma, and follicular lymphoma were denied by immunostaining for CD5, CD10,
CD23, and cyclin D1. CD15 and CD30 were negative. The lymphoma cells were positive focally for p53 protein, and Ki-67 labeling ranged from 78% to 99%.

The two cases (0.47%) of GIST were serosal tumor (Figure 6A) in one case (45 mm in diameter) and submucosal tumor in another case (55 mm in diameter). Both cases consisted of spindle cell type (Figure 6B). Mitotic figures were 6 per 50 high power field (HPF) in one case and 8 per 50 HPF in another case. Ki-67 labeling was 15% and 24%, respectively. Immunohistochemically, tumor cells were positive for KIT (Figure 6C), CD34 (Figure 6D), PDGFRA (Figure 6E), and negative for desmin, smooth muscle antigen, and S100 protein. The molecular analysis showed a point mutation of KIT gene exon 9 and a deletion of KIT gene exon 11. No mutations were found in PDGFRA genes.

Of the 3 metastatic carcinomas, one was a metastasis from prostatic adenocarcinoma positive for prostate-specific antigen (Figure 7A and 7B), and the remaining two were adenocarcinomas of unknown primary sites.

Discussion

In the present study, the author reviewed 1,464 consecutive pathologic specimens of the rectum in our laboratory in the last 10 year.

The results of rectal adenocarcinoma were compatible with previous study. Early adenocarcinoma of the rectum was found in 37 among 367 cases. The early carcinoma was free of lymphovascular invasions, suggesting that the good prognosis relative to advanced adenocarcinoma. In the present study, 24 cases of mucinous adenocarcinoma and 6 cases of signet ring cell carcinoma were present among the 367 rectal carcinomas. These two kinds of adenocarcinoma is relatively rare in the rectum, and different from ordinary rectal adenocarcinoma with respect to microsatellite instability [14] mismatch repair enzyme [15] BRAF, KRAS, LOH, [16], and poor prognosis [17], relative to ordinary rectal adenocarcinoma. The present study presented a case of squamous cell carcinoma of the rectum. It was located only in the mucosa. The squamous cell carcinoma of the colorectum is extremely rare,
Rectal malignant conditions

and only a few cases are reported in the colon but not in the rectum in the literatures [18, 19]. The histogenesis of squamous cell carcinoma of the rectum is unclear, but it may be possible that totipotential stem cells differentiated into squamous cell carcinoma of the rectum.

The malignant transformation of adenoma in the colorectum is well known. It is well established that colorectal carcinogenesis has two pathways; adenoma-carcinoma sequence and de novo carcinogenesis [2, 20]. In the former, multistep carcinogenesis is considered; each step is accompanied by mutations of oncogenes such as RAS and of tumor suppressor genes such as p53 [2, 20, 21]. Therefore, colorectal adenomas are precancerous lesions [2, 20, 21]. In the present study, carcinoma in adenoma was largely observed in adenoma > 15 mm, suggesting a correlation between the malignant transformation and adenoma size. In the present study, carcinoma in adenoma was most frequent in tubular adenoma, followed in order by tubulo-villous adenoma and villous

adenoma. According to WHO blue book [2], carcinomatous transformation is most frequent in villous adenomas, followed in order by tubulovillous adenomas and tubular adenomas. The WHO book also showed that adenomas > 2cm had malignant foci in 30-50%. In addition, the WHO book showed adenomas < 2cm had malignant foci in 1-10%. In the present study, p53 protein is frequently recognized in carcinoma in adenoma, suggesting the malignant transformation is associated with p53 mutations. Much more studies of molecular alteration of oncogenes and antioncogens are required.

Carcinoids (neuroendocrine tumors) are well known to occur in the rectum [1, 2]. In the present study, 6 cases of typical carcinoids immunoreactive for neuroendocrine antigens were found. In the present study, 1 case of high grade neuroendocrine carcinoma compatible with small cell carcinoma was recognized. This tumor was positive for neuroendocrine markers, KIT and PDGFRA. No mutations of KIT and PDGFRA were noted. Rectal high grade neuroendocrine tumors are extremely rare, only a few reports are seen in the literature [22-24]. Recently, high grade neuroendocrine carcinoma is known to express KIT and PDGFRA [8, 10, 25-28]. However, no mutations of KIT and PDGFRA have been identified in small cell carcinomas [25-28], as in the present study.

Malignant lymphoma of the rectum is relatively rare. In the present series, 3 cases of lymphoma were identified. All the 3 cases were immunohistochemically-proven diffuse large B-cell lymphoma. Wong and Eu [29] described that the frequency of colorectal lymphoma was 0.44% (14 of 3199 cases), and most of them were diffuse large B-cell lymphoma. Fan et al. [30] described that the frequency of colorectal lymphoma was 0.48 % (37/7,648) in colorectal malignancies, and that they consisted of 29 high grade lymphomas and 8 non-high grade lymphomas. The frequency in the present series was 0.71% (3 of 423 cases) of all rectal malignancies. Much more studies are needed in the rectal malignant lymphoma.

Rectal GIST is a rare tumor relative to gastrointestinal GIST. Miettinen and Lasota [31] reported that the frequency of GIST was as follows: stomach (60%), jejunum and ileum (30%), duodenum (4-5%), rectum (4%), and colon and appendix (1-2%). The frequency of rectal GIST of the present series was 0.47% (2 of 423 cases). There are a few case reports of rectal GIST [32, 33]. GIST is characterized by positive immunoreaction of KIT (CD117) and CD34, and by genetic mutations of KIT or PDGFRA genes [8-13]. The KIT and PDGFRA mutations are mutually exclusive. The 2 cases of the present series were positive for KIT, CD34 and PDGFRA, and showed KIT gene mutations, one in exon 9 and another in exon 11. GIST is a potentially malignant tumor; the malignant potential depends on tumor type (spindle vs epithelioid), tumor size, mitotic figures, necrosis, and Ki-67 labeling. According to the consensus report of GIST by Fletcher et al. [34], the malignant potential of GIST depends on tumor size and mitotic counts. In very low malignant risk group,
tumor size is less than 2 cm and mitotic counts are less than 5 per 50 high power field (HPF). In low malignant risk group, tumor size is 2cm < 5cm, and mitotic counts are < 5/50 HPF. In intermediate risk group, tumor size is 5cm < 10cm, and mitotic counts are < 5/50 HPF. In high risk group, tumor size is > 10 cm, and mitotic counts are > 10/50 HPF [34]. In the present study, according to mitotic counts and tumor size [34], the malignant risk was intermediate or low risk.

Conflict of interest statement

The author has no conflict of interest.
